²Environmental Science Division, Argonne National Laboratory

Abstract. Farming is using more terrestrial ground with increases in population and the expanding use of agriculture for non-nutritional purposes such as biofuel production. This agricultural expansion exerts an increasing impact on the terrestrial carbon cycle. In order to understand the impact of such processes, the Community Land Model (CLM) has been augmented with a CLM-Crop extension that simulates the development of three crop types: maize, soybean, and spring wheat. The CLM-Crop model is a complex system that relies on a suite of parametric inputs that govern plant growth under a given atmospheric forcing and available resources. CLM-Crop development used measurements of gross primary productivity and net ecosystem exchange from AmeriFlux sites to choose parameter values that optimize crop productivity in the model. In this paper we calibrate these values in order to provide a faithful projection in terms of both plant development and net carbon exchange, using a Markov chain Monte Carlo technique.

soils in the Community Land Model (CLM) version 3.5 to become cold biased in CLM4.0. Although testing of ESMs is extensive, ensuring after new developments are merged that the model can still perform with limited (if any) degradation, on rare occasions model behavior can be negatively affected. The strong nonlinearity of such models also makes parameter fitting a difficult task; and as global models are developed by several different user groups simultaneously, combinations of multiple alterations make identifying the specific cause that leads to a new model output challenging. The CLM has been augmented with a CLM-Crop extension that simulates the development of three crop types: maize, soybean, and spring wheat. The CLM-Crop model is a complex system that relies on a suite of parametric inputs that govern plant growth under a given atmospheric forcing and available resources. CLM-Crop development used measurements of gross primary productivity (GPP) and net ecosystem exchange (NEE) from AmeriFlux sites to choose parameter values that optimize crop productivity in the model.

1 The CLM-Crop Model

Development of Earth system models (ESMs) is a challenging process, involving complex models, large input datasets, and significant computational requirements. As models evolve through the introduction of new processes and through improvement of traditional algorithms, the ability of the models to accurately simulate feedbacks between coupled systems improves, although results may not have the desired impact on all areas. For example, Lawrence et al. (2012) estimate that changes to the hydrology parameterization may be responsible for the warm bias in high-latitude

Global climate models (GCMs) have historically been tuned or calibrated to meet certain requirements, such as balancing the top of the atmosphere radiation budget (Bender, 2008; Hourdin et al., 2012; Mauritsen et al., 2012). Various techniques have been applied to models to adjust parameters, including data assimilation (Pauwels et al., 2007), applying an ensemble Kalman filter (EnKF) (Hargreaves et al., 2004; Annan et al., 2005; Evensen, 2009), and using a sampling algorithm such as multiple very fast simulated annealing (MVFSA) (Yang et al., 2012), which can be used to calibrate one or many parameters at a time in coupled or uncoupled modes. Most calibration strategies can be traced back to a Bayesian approach that in most cases is simplified (MVFSA) or augmented with assumptions that make the problem tractable (EnKF). Tuning parameters that are not directly observed casts the problem into an inverse problem (Tarantola, 2005), which is in general a challenging problem when the data are sparse, the models are complex, and the

Preprint ANL/MCS-P3054-1112

state space is large. This is the case for ESMs as well as for the CLM-Crop model.

Our goal is to calibrate some of the CLM-Crop parameters in order to improve model projection of plant development and carbon fluxes. To this end, we propose a new calibration procedure based on a Bayesian approach, which is implemented through a parallel Markov chain Monte Carlo (MCMC) technique (Chib and Greenberg, 1995; Solonen et al., 2012; Craiu et al., 2009). MCMC is used to generate samples (of parameter values, in our case) drawn from a (posterior) distribution that represents updated parameter values based on observational information. We present the results from a twin experiment (self-validation) and calibration results and validation using real observations from AmeriFlux towers for two sites in the midwestern United States, rotating corn and soybean. The improved model will enhance our understanding of how climate will affect crop production and resulting carbon fluxes, and additionally, how cultivation will impact climate.

1.1 Description of the CLM-Crop Model

CLM-Crop was designed and tested in the CLM3.5 model version (Drewniak et al., 2012). The crop model was created to represent crop vegetation similarly to natural vegetation for three crop types: maize, soybean, and spring wheat. The model simulates GPP and yield driven by climate, in order to evaluate the impact of climate on cultivation and the impact of agriculture on climate. Crops are modeled within a grid cell sharing natural vegetation; however, they are independent (i.e., they do not share the same soil column). This approach allows management practices, such as fertilizer, to be administered without disturbing the life cycle of natural vegetation.

Although the design of the crop model fits within the framework of natural vegetation, crops have a significantly different growing scheme, separated into four phases: planting, emergence, grain fill, and harvest. Each phase of growth changes how carbon and nitrogen are allocated to the various plant parts: leaves, stems, fine roots, and organs. During planting, carbon and nitrogen are allocated to the leaf, representative of seed. This establishes a leaf area index (LAI) for photosynthesis, which begins during the emergence phase. The emergence phase allocates carbon and nitrogen to leaves, stems, and roots using functions from the Agro-IBIS model (Kucharik and Brye, 2003). During the grain fill stage, decreased carbon is allocated to leaves, stems, and roots in order to fulfill organ requirements. When maturity is reached, harvest occurs: all organs and 60-70% of the leaves and stems are harvested; and the remaining leaves, stems, and roots are turned into the litter pool.

The allocation of carbon to each plant part is driven largely by the carbon-nitrogen (CN) ratio parameter assigned to each plant segment. CLM first calculates the potential photosynthesis for each crop type based on the incoming solar radia-

tion and the LAI. The total nitrogen needed to maintain the CN ratio of each plant part is calculated as plant demand. If soil nitrogen is sufficient to meet plant demand, potential photosynthesis is met; however, if soil nitrogen is inadequate, the total amount of carbon that can be assimilated is down-scaled.

During the grain fill stage, a nitrogen retranslocation scheme is used to fulfill nitrogen demands by mobilizing nitrogen in the leaves and stems for use in organ development. This scheme uses alternate CN ratios for the leaf and stem to determine how much nitrogen is transferred from the leaves and stems into a retranslocation storage pool. The total nitrogen transferred at the beginning of the grain fill stage from the leaf and stem is represented by

$$\text{retransn}_{\text{leaf}} = \frac{C_{\text{leaf}}}{\text{leafcn}} - \frac{C_{\text{leaf}}}{\text{fleafcn}}, \quad (1)$$

$$\text{retransn}_{\text{stem}} = \frac{C_{\text{stem}}}{\text{stemcn}} - \frac{C_{\text{stem}}}{\text{fstemcn}}. \quad (2)$$

C_{leaf} and C_{stem} are the total carbon in the leaf and stem, respectively; leafcn and stemcn are the pregrain fill CN ratios for the leaf and stem; and fleafcn and fstemcn are the post-grain fill CN ratios for the leaf and stem.

In addition to the above, CLM-Crop has a fertilizer application, dynamic roots, and soybean nitrogen fixation, described by Drewniak et al. (2012). Planting date and time to maturity are based on the Crop Calendar Dataset (Sacks et al., 2010).

CLM-Crop was calibrated against AmeriFlux data for the Mead, NE, and Bondville, IL, sites' plant carbon measurements, for both maize and soybean, using optimization techniques to fit parameters. When available, parameter values were taken from the literature or other models. Remaining parameters were derived through a series of sensitivity simulations designed to match modeled carbon output with AmeriFlux observations of leaf, stem, and organ carbon at the Bondville, IL, site and total plant carbon at the Mead, NE, (rainfed) site.

When CLM-Crop was ported into the CLM4 framework, the parameter values were no longer optimized as a result of various changes in model processes that affected how crops fit into the model framework. Therefore, we needed to retune the model parameters that represented crops with a more sophisticated approach described later in this paper.

1.2 Parameters Affecting the Crops

Over 100 parameters are defined in CLM4 to represent crops. Many of these parameters are similar to those that govern natural vegetation, but some are specific to crops. These parameters define a variety of processes, including photosynthesis, vegetation structure, respiration, soil structure, carbon nitrogen dynamics, litter, mortality, phenology, and more. To add further complication, parameters are assigned in various

parts of the model; some parameters are defined in an external physiology file, some are defined in surface datasets, and others are hardcoded in the various subroutines of CLM4.

Performing a full model calibration for all parameters would be a monumental task, so we began our calibration process by narrowing down the parameters that are used only in crop functions or might have a large influence on crop behavior. Of this list, parameter values can be fixed across all vegetation types (or crop types), vary with crop type, or vary spatially and by crop type. We chose to limit the parameters to those that are either constant or vary with crop type.

Although from the literature we have minimum and maximum estimates for some variables, some parameters do not have observed ranges, as they were optimized for use in CLM based on performance. Therefore, determining a full range of acceptable values was difficult for several parameters, and in some cases not possible. Of the full list of parameters in need of calibration, we began our approach with the six parameters listed in Table 1 that have a large influence on crop productivity and have the greatest uncertainty because the values are based on optimization from a previous model version. These six parameters are the carbon nitrogen ratios for the various plant parts (leaf, stem, root, and organ). Since the leaf and stem account for nitrogen relocation during grain fill, they are represented by two separate CN ratios, to separate pre- and postgrain fill stages of plant development. They influence how carbon and nitrogen are allocated, thereby impacting growth, nutrient demand, photosynthesis, and so on, and are included as part of the physiology data file.

1.3 Description of the Observational Data Set

We used observations from the Bondville, IL AmeriFlux tower located in the midwestern United States using an annual no-till corn-soybean rotation; a full site description is given by Meyers and Hollinger (2004). The site has been collecting measurements since 1996 of wind, temperature, humidity, pressure, radiation, heat flux, soil temperature, CO₂ flux, and soil moisture. Soybeans were planted in 2002 and 2004 and corn was planted in 2001, 2003, and 2005. We used daily averaged eddy covariance measurements of NEE and derived GPP in our model calibration procedure, which are categorized as Level 4 data published on the AmeriFlux site, gap filled by using the procedure outlined by Hollinger et al. (2005). In addition, biomass information (which we convert to carbon) and LAI have been collected for years 2001-2005 for the various plant segments, including leaf, stem, and organ, which are reported in the AmeriFlux website (<http://public.ornl.gov/ameriflux>).

The time-dependent observations are denoted by $y = \{\text{GPP, NEE, ORGANC, LEAFC, STEMC, LAI}\}$. Because of uncertainties in irrigation, fertilization use, and planting date we focused on the peak observed values as well as the growth slope. To remove the atmospheric induced noise in the NEE and GPP measurements we filtered the time series

by applying a moving average operator with a width of 30 days. These operations are denoted by the map

$$H_y(y) = \{\max(\bar{y}), \text{slope}(\bar{y})\}, \quad (3)$$

$Y = H_y(y)$, where \bar{y} represents the filtered y and the slope is calculated in the beginning of the plant emergence phase.

1.4 Initial Conditions and Spinup

CLM requires a spinup to obtain balanced soil carbon and nitrogen pools, which are responsible for driving decomposition and turnover. CLM is spun up by using the method provided by Thornton and Rosenbloom (2005), with crops simulated as grass, such that final soil carbon pools are reflective of natural vegetation. After the initial spinup is complete, grid cells growing crops are converted from grass to represent the appropriate amount of land surface occupied by agriculture. The model is run an additional 200 years to rebalance the soil pools.

The meteorological forcing data used for the spinup is from the Bondville, IL flux tower site. The model is run in point mode, meaning only one grid cell is simulated, at a resolution of 0.5 degrees x 0.5 degrees. Since we do not have the meteorological data necessary to cover the entire spinup period, we cycle continuously through the period of data from 1996 to 2007 available for this site.

2 Calibration Strategy

We represent the CLM-Crop model by $f(x;\theta)$, where θ are the time-independent parameters that we wish to calibrate and x are the internal states of the model. We consider different sets of calibration parameters according to their perceived level of uncertainty and importance in the crop development processes. The first set consists of plant specific physiological parameters: leafcn, fleafcn, fstemcn, organcn, frootcn, and livewdcn (see Table 1 and Sect. 1.2 for details).

The model calibration strategy aims to merge model predictions that depend on parameters θ with observational datasets. Here we denote the model output by $F(\theta) = \mathcal{H}(f(x;\theta))$, where \mathcal{H} is a function that maps the model output to observation space Y obtained similarly with the procedure described in Sect. 1.3.

We assume that the relationship between observation data and the true process follows a relationship of type

$$Y = F(\theta^*) + \varepsilon,$$

where θ^* are the perfectly calibrated parameters and ε represents the observational errors. This holds under the assumption that the model is a perfect representation of reality (Kennedy and O'Hagan, 2001). The problem statement can be extended to account for imperfect models, but then the

statistical description of ε tends to become much more complicated. Therefore, for this study we start by considering a perfect model assumption.

Following a Bayesian approach, we assume a prior distribution on the calibration parameters:

$$\log(\pi(\theta)) = -\frac{1}{2}(\theta - \bar{\theta})^T \Sigma_{\theta}^{-1}(\theta - \bar{\theta}) - K_{\theta}, \quad (4)$$

where $\bar{\theta}$ are the default parameters, $K_{\theta} = \frac{1}{2} \log(\det(\Sigma_{\theta})) + \frac{n_{\theta}}{2} \log(2\pi)$, and $n_{\theta} = \dim(\theta)$. We define the likelihood as

$$\log(\pi(y|\theta)) = -\frac{1}{2}(F(\theta) - H(y))^T \Sigma_{\text{obs}}^{-1}(F(\theta) - H(y)) - K_y,$$

where $\Sigma_{\text{obs}} = \text{Cov}(\varepsilon)$ and K_y is defined similarly with K_{θ} . The calibration result in the posterior distribution

$$\pi(\theta|y) \propto \pi(y|\theta)\pi(\theta). \quad (5)$$

We use the Metropolis Hastings algorithm to estimate the posterior distribution (Chib and Greenberg, 1995). To accelerate and diagnose the convergence, we implemented a parallel version of the algorithm that consists in running several Markov chains in parallel while adjusting a Gaussian proposal distribution according to their spread (Solonen et al., 2012; Craiu et al., 2009). This algorithm and convergence diagnostics are briefly described in Appendix A.

3 Results

In this section we present our calibration results for parameters described in Sect. 1.2 by using observations detailed in Sect. 1.3. In this study we focus only on the CN parameters affecting the soy crop and restrict our calibration to year 2004. With these calibrated parameters we perform a validation experiment by using the data from year 2002. Moreover, we perform a twin experiment that consists in generating artificial data by using some control parameter values, then perturbing those parameters and applying the calibration strategy to recover the control values.

3.1 Validation of the Method

We begin with a twin experiment with the aim of validating the parallel MCMC strategy applied in this study. We generate artificial observations by using the default parameter values and then perturb the parameters. We apply the calibration strategy using the perturbed parameters as initial guesses and the artificial observations; our aim is to recover the default parameters. In Fig. 1a we show the box plot summary of the calibrated parameters. We note an almost perfect fit between the calibrated parameters and their default values, indicating that the method used in this study is appropriate.

3.2 Calibration Using Real Data

In our next experiment we calibrate the six parameters listed in Table 1. The observational operator Eq. (3) is defined by taking the annual maximum of LEAFC, TLAI, ORGANC, STEMC, GPP, and -NEE; and the slope of LEAFC, STEMC, GPP, and NEE from planting to the peak value. We applied the MCMC calibration strategy described in Appendix A. A simulated year takes about 2 minutes in real time on our computers, and we are able to run 8 instances in parallel on the same computational node (one per computational core). We computed 13,401 samples per chain for 8 parallel chains and discarded the first 6,000 samples for burn-in. The final convergence diagnostic, MPSRF (see Appendix A), was 1.009, where 1 is the optimal value, and below 1.2 is considered a good value in practice (Gilks et al., 1996).

Our newly calibrated parameter values are shown as a box plot summary of the parameter probability density function in Fig. 1b compared with initial values. Our first estimate of parameter values was overestimated for leafcn, fleafcn, fstemcn, and organcn but is underestimated for frootcn and livewdcn. With the exception of leafcn and livewdcn, however, all initial parameter values fall within the range of probability of the calibrated parameters. This result gives us confidence that (at least some of) the initial values were within an acceptable range. We also note that the parameters that are not within the calibrated range (leafcn and livewdcn) have not been observed and were based solely on optimization with the CLM3.5 crop model.

We then used the median value of the posterior parameter distribution as the final calibrated parameter values, to run the simulation for year 2004. In Fig. 2, we plot the observations, the model output using the default parameters, and the calibrated output. We note that the performance metric used for this calibration was the peak value and the initial slope in the growth season. Based on this measure, the calibrated output shows a much better fit than the default values show.

3.3 Validation of Real Data Results

To validate the generalization potential of our calibration we perform a one-way validation. We use the calibrated plant parameters result of soybean data of 2004 (Sect. 3.2) to predict the observables obtained in 2002. In Fig. 3 we plot the model time series with observations and the control output of 2002. Here we note good performance in the success metric established for this study. There is, however, a temporal shift in the time series of 2002 that can be attributed to a mismatch in the planting dates. As noted in Sect. 1.1, the planting date in CLM-Crop is fixed based on data from Sacks et al. (2010) and therefore not subject to change based on seasonal conditions such as temperature and precipitation. Although this is being modified in future versions of the model, the yearly planting date at global scale is not available, so our analysis focuses on the slope of the growth and the peak of the GPP

and carbon, which indeed show much improvement from the default parameter values. The uncertainty levels represented by the size of the boxes in Fig. 1 indicate the 50% spread of the parameter values around the median. We note that the distribution seems to be relatively symmetric, and in general, the relative uncertainty seems to be about the same.

4 Discussion

In this paper, we sought to improve CLM-Crop model performance by parameter calibration of a subset of model parameters governing the carbon and nitrogen allocation to the plant components. By using an MCMC approach, we were able to improve the model-simulated GPP, NEE, and carbon biomass to leaf, stem, and organ with the new parameter values. In addition, we demonstrated that the calibrated parameters are applicable across alternative years and not solely representative of one year.

This simulation does have a few limitations stemming from a lack of observation data. Currently our results are suitable at one site across multiple years; testing at multiple sites would give a better indication of how well the model can perform globally, or even across a region. However, the limited data over agricultural sites constrains our ability to determine parameter values that are relevant at a global scale. Also, our use of fixed planting dates does not allow the model to modify when planting occurs as a farmer would in situ. Thus, the model can over- or underestimate the planting date, which, if significant, could influence the growth cycle and resulting carbon fluxes. In addition, CLM-Crop does not have crop rotation, which is common across agricultural landscapes, including in the observation dataset. Crop rotation can modify below-ground carbon and nitrogen cycling that would have an impact on crop productivity through nutrient availability. While we would like to include this feature, CLM does not currently have the capability to support this function.

Our approach has focused on one crop type, soybean, with the intent of determining the effectiveness of the MCMC method in performing parameter calibration. We consider the results promising and, as part of future work, hope to expand this research to additional years, crop types, and other parameters. Many other variables are of interest, including specific leaf area, fertilization rate, timing of the growth stages, respiration rates, and a few other parameters related to photosynthesis. As the model continues to evolve with the addition of new or improved processes, we also may need to revisit the parameter choices and evaluate their appropriateness.

The introduction of new datasets documenting agriculture productivity or carbon mass will also allow us to determine the applicability of our new parameter values across regions. In general, the calibration results depend on an accurate specification of the observational errors. In this study we did not have access to any information regarding the measure-

ment process and, therefore, assumed a certain observational noise. These calibration results can be sharpened by annotating the observational data with levels of confidence. The calibration strategy presented in this study has the potential to improve model performance by helping modelers define parameters that are not often measured or documented.

Appendix A Metropolis Hastings Algorithm and Convergence Diagnostics

The general idea of the Metropolis Hastings algorithm is to generate a series of samples that are linked in a Markov chain (where each sample is correlated only with the directly preceding sample). At sufficiently long times, the distribution of the generated samples matches the distribution. The algorithm essentially works as follows (this is actually a description of the Metropolis algorithm, a special case of Metropolis Hastings).

Suppose that the target density is $\pi(x)$. Pick an arbitrary probability density $Q(x'|x_t)$ (the proposal density or jumping distribution), which suggests a new sample value given a sample value. Suppose that this proposal density is symmetric. Start with some arbitrary point as the first sample. Then proceed as follows:

- Generate a proposed new sample value from the jumping distribution $Q(x'|x_t)$.
- Calculate the acceptance ratio $\alpha = \frac{\pi(x')}{\pi(x_t)}$
- If $\alpha > 1$, accept by setting $x_{t+1} = x'$.
- Else, pick a uniformly distributed random number u between 0 and 1, and if $u < \alpha$ set $x_{t+1} = x'$, else set $x_{t+1} = x_t$.

The convergence test is coded according to [Brooks and Gelman \(1998\)](#). Suppose that the sample point (1D case) is denoted as $s_{i,j}, i = 1, \dots, n, j = 1, \dots, m$. Denote that $\bar{s} = \frac{1}{n} \sum_{i=1}^n \sum_{j=1}^m s_{i,j}$ and $\bar{s}_j = \frac{1}{m} \sum_{i=1}^n s_{i,j}$. The estimate of variance within-chain is $W = \frac{1}{n} \sum_{i=1}^n \sum_{j=1}^m (s_{i,j} - \bar{s}_j)^2$. Then the estimate of variance between chains is given by $\frac{B}{n} = \frac{1}{m-1} \sum_{j=1}^m (\bar{s}_j - \bar{s})^2$ and the posterior variance-covariance matrix by $V = \frac{n-1}{n} W + \frac{B}{n}$. The multivariate scale reduction factor PSRF (or MPSRF) – the convergence indicator – is $R = \frac{V}{W}$.

For the multidimensional case, the estimate of variance within-chain is $W = \sum_{i=1}^n \sum_{j=1}^m (s_{i,j} - \bar{s}_j)(s_{i,j} - \bar{s}_j)^T$. The estimate of variance between chains is calculated as $\frac{B}{n} = \frac{1}{m-1} \sum_{j=1}^m (\bar{s}_j - \bar{s})(\bar{s}_j - \bar{s})^T$ and the estimate of the posterior variance-covariance matrix is $V = \frac{n-1}{n} W + (1 + \frac{1}{m}) \frac{B}{n}$. Finally, the multivariate scale reduction factor PSRF (or MPSRF) is $R = \max_a \frac{a^T V a}{a^T W a}$, that is, $R = \frac{n-1}{n} + \frac{m+1}{m} \lambda_1$, where λ_1 is the largest eigenvalue of the symmetric, positive definite matrix $W^{-1} \frac{B}{n}$.

In this study we used a parallel MCMC implementation (Solonen et al., 2012; Craiu et al., 2009). In particular, the algorithm is the same for each chain, but the proposal distribution Q is determined from the history of the parallel chains.

Table 1. Parameters chosen for calibration

Parameter Name	Parameter Description
leafcn	Leaf CN ratio; pregrain fill
fleafcn	Leaf CN ratio; postgrain fill
livewdcn	Stem CN ratio; pregrain fill
fstemcn	Stem CN ratio; postgrain fill
frootcn	Fine root CN ratio
organcn	Organ CN ratio

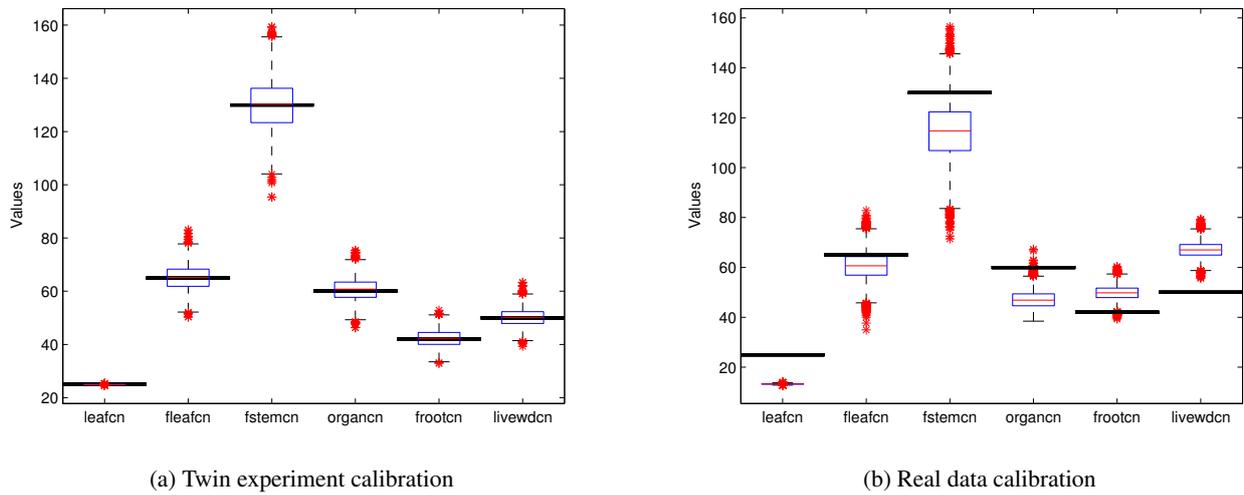

Fig. 1. Calibrated C/N parameters for 2004 for (a) the twin experiment using artificial observations and (b) the real data calibration. The solid black line indicates the default values, and the thin red line indicates the median value for the parameter posterior distribution. The median value was used as the final calibrated parameter value.
