Abstract

We analyze the stability properties of an approximate algorithm for moving horizon estimation (MHE). The strategy provides instantaneous state estimates and is thus suitable for large-scale feedback control. In particular, we study the interplay between numerical approximation errors and the convergence of the estimator error. In addition, we establish connections between the numerical properties of the Hessian of the MHE problem and traditional observability definitions. We demonstrate the developments through a simulation case study.

Keywords: estimation, stability, large-scale, observability, nonlinear programming

1 Introduction and Basic Notation

In this paper, we consider the problem of state estimation for nonlinear discrete-time systems of the form

\begin{align}
  x_{t+1} &= f(x_t, u_t) + \xi_t, \quad t \geq 0 \\
  y_t &= h(x_t) + \eta_t, \quad t \geq 0,
\end{align}

where \( x_t \in \mathcal{X} \subseteq \mathbb{R}^{n_x} \) is the state of the system, \( u_t \in \mathcal{U} \subseteq \mathbb{R}^{n_u} \) are the inputs, and \( y_t \in \mathbb{R}^{n_y} \) are the measured outputs. Symbols \( \xi_t \in \Xi \subseteq \mathbb{R}^{n_\xi} \) and \( \eta_t \in \mathcal{H} \subseteq \mathbb{R}^{n_\eta} \) denote bounded process and measurement noise disturbances, respectively. The nonlinear mappings \( f : \mathbb{R}^{n_x} \times \mathbb{R}^{n_u} \to \mathbb{R}^{n_x} \) and \( h : \mathbb{R}^{n_x} \to \mathbb{R}^{n_y} \) represent the state and output models, respectively.

Moving horizon estimation (MHE) strategies use a moving measurement window,

\[ \mathbf{I}_t^T = [I_y^T, I_u^T] = [y_t-N, ..., y_t-1, y_t, u_t-N, ..., u_t-1], \quad t \geq 0 \]

(2)

to compute estimates \( \hat{x}_t \) of the true state \( x_t \). Here, \( N \) is the size of the moving window, and \( \mathbf{I}_t \in \mathbb{R}^{Nn_y+(N-1)n_u} \) is the information vector at time \( t \). The MHE formulation used in

*Preprint ANL/MCS-P1644-0609
this work has the following form:

\[
\begin{align*}
\min_{z_0} & \quad J(z_0, \hat{x}^o_{t-N}, I_t) := \mu \|z_0 - \hat{x}^o_{t-N}\|^2 + \sum_{k=0}^{N} \|y_{t-N+k} - h(z_k)\|^2 \\
\text{s.t.} & \quad z_{k+1} = f(z_k, u_{t-N+k}), \quad k = 0, \ldots, N - 1 \\
& \quad z_k \in \mathcal{X}, \quad k = 0, \ldots, N,
\end{align*}
\]

(3a)

(3b)

(3c)

where the objective function (3a) incorporates the arrival cost and the least-squares output errors along the horizon, (3b) is the state model, and (3c) are the constraints. The optimal solution of this nonlinear programming problem (NLP) provides the state trajectory \([z_0^o, \ldots, z_N^o]\) from which we extract the initial state estimate \(\hat{x}^o_{t-N} \leftarrow z_0^o\) and, implicitly, the current state \(\hat{x}_t^o \leftarrow z_N^o\). In the following, we will use only the initial state estimate to refer to the solution of the MHE problem. Accordingly, the estimator error at the current time \(t\) is defined as \(e^o_{t-N} := \hat{x}^o_{t-N} - x_{t-N}\). The optimal cost is denoted as \(J(\hat{x}^o_{t-N}, \bar{x}^o_{t-N}, I_t)\). The symbol \(\bar{x}^o_{t-N}\) denotes the reference or prior value of the initial state; \(\mu\) is a regularization parameter fixed by design. At the next time step \(t + 1\), once we have the new measurements \(y_{t+1}\) and \(u_t\), we shift the measurement window forward: \(I_{t+1}^T = [y_{t-N+1}, \ldots, y_t, y_{t+1}, u_{t-N+1}, \ldots, u_t]\). In addition, the reference initial state is updated as \(\bar{x}^o_{t-N+1} \leftarrow f(\hat{x}^o_{t-N}, u_{t-N})\), and the next MHE problem is solved to optimality. In the following, we will refer to the above strategy as the optimal MHE algorithm.

One of the main problems associated with MHE is to establish stability conditions for the estimation error \(e_t := \hat{x}_t - x_t\), \(t \geq 0\). Different stability studies have been reported. In [1], the authors derive stability conditions for an estimator formulation assuming that the output errors vanish at the solution. With this, the estimator can be cast as a system of nonlinear equations, and stability properties can be established using fixed-point arguments. The analysis in [2] establishes stability by using Lyapunov arguments for an optimization-based estimator that penalizes only least-squares output errors. This work was extended in a comprehensive stability analysis presented in [3]. Here, the authors analyze the MHE problem as a forward dynamic programming approximation of the optimal batch estimator. Using this connection, they introduce the notion of the arrival cost and establish stability conditions using Lyapunov arguments. Their MHE strategy uses a more general least-squares objective than (3a), including prior and noise covariance matrices. This permits the authors to establish statistical properties of the estimator. In addition, the strategy computes estimates of the process noise sequences \(\xi_t\) and handles constraints. The stability analysis in [4] uses the above MHE formulation (3). In this formulation, process noise \(\xi_t\) is treated as a non-estimable disturbance. In addition, the arrival cost uses a fixed prior diagonal matrix of the form \(\mu \cdot \mathbb{I}_{n_x}\), \(\mu \geq 0\). As expected, the stability and statistical properties of this estimator are less general compared to those in [3]. However, this formulation permits a transparent analysis of the impact of the system properties on the stability of the estimator from which much insight can be obtained. Motivated by this, we use this formulation and associated stability arguments here.

A problem that arises in most practical MHE implementations is that the NLP (3) is a computationally intensive optimization problem. For instance, when MHE is used for feedback control, the solution time of the NLP introduces a nonnegligible feedback delay.
that deteriorates closed-loop performance [5]. In this work, we consider an approximate MHE formulation with minimal on-line computational effort and analyze its stability properties. The strategy is a simplification of the advanced-step MHE estimator presented in [6] in which nearly instantaneous approximate estimates are constructed by using reference solutions computed in background (i.e., between sampling times). We analyze the impact of numerical approximation errors on the stability properties of the algorithm and contrast these with those of the optimal MHE algorithm. In addition, we establish connections between the observability properties of the nonlinear system and the properties of the MHE problem. We illustrate the developments using a simulation case study.

The paper is structured as follows. In Section 2 we derive the approximate MHE algorithm. In Section 3 we establish system and observability properties. In Section 4 we derive stability conditions for the optimal and approximate MHE estimators. In Section 5 we present the numerical study. We close the paper with concluding remarks and directions of future work.

## 2 Approximate MHE Algorithm

To construct the approximate MHE algorithm, we recognize that, at time step $t-1$, we can use the current state estimate $\hat{x}_t$ and input $u_{t-1}$ to predict the future state and associate measurement $\hat{x}_t = f(\hat{x}_{t-1}, u_{t-1})$ and $\hat{y}_t = h(\hat{x}_t)$, respectively. With these, we can use the predicted information vector $I_t = [\bar{I}_t^y, I_t^u]^T = [y_{t-N}, ..., y_{t-1}, \hat{y}_t, u_{t-N}, ..., u_{t-1}]^T$ to solve, between sampling times, the background MHE problem:

$$
\min_{z_0} \quad J(z_0, \bar{x}_{t-N}, I_t) := \mu \|z_0 - \bar{x}_{t-N}\|^2 + \|\hat{y}_t - h(z_N)\|^2 + \sum_{k=0}^{N-1} \|y_{t-N+k} - h(z_k)\|^2 \quad \text{(4a)}
$$

s.t. $z_{k+1} = f(z_k, u_{t-N+k}), \quad k = 0, ..., N-1$

$$
\quad z_k \in \mathcal{X}, \quad k = 0, ..., N. \quad \text{(4b)}
$$

Using the solution of this problem $\hat{x}_{t-N}(I_t)$, we construct an on-line correction formula of the form

$$
\hat{x}_{t-N}(I_t) = \hat{x}_{t-N}(I_t) + K_t^o (I_t - I_t) \quad \text{(5)}
$$

With this, we can compute a fast on-line estimate as soon as the true measurement $y_t$ becomes available. Here, $K_t^o$ is a gain matrix that can be constructed by using NLP sensitivity and the Karush-Kuhn-Tucker matrix of the MHE problem evaluated at the solution of the background MHE problem (see the next section). In [6], it has been shown that this matrix is a Kalman-like gain matrix. The approximate state generated by the correction step at time $t$ is denoted as $\hat{x}_{t-N}(I_t)$. This has an associated cost $J(\hat{x}_{t-N}(I_t), \bar{x}_{t-N}, I_t)$ and error,

$$
\epsilon_t := J(\hat{x}_{t-N}(I_t), \bar{x}_{t-N}, I_t) - J(\hat{x}_{t-N}(I_t), \bar{x}_{t-N}, I_t). \quad \text{(6)}
$$

The current estimation error is $\epsilon_{t-N} := \hat{x}_{t-N} - x_{t-N}$. At the next time step, the reference state is updated as $\hat{x}_{t-N+1} \leftarrow f(\hat{x}_{t-N}, u_{t-N})$. In the following, we will refer to this algorithm as the approximate MHE algorithm.
The approximate MHE strategy can significantly reduce the on-line solution time because the expensive computational tasks are performed between sampling times while the correction step (5) can be computed almost instantaneously [7, 6]. However, a problem that arises in approximate MHE schemes is that the correction step introduces a numerical approximation error $\epsilon_t$ that is propagated at each time step through the reference initial state. In the next sections, we investigate under which conditions we can guarantee stability even in the presence of these numerical errors. In addition, we analyze the interplay between these errors and the dynamics of the estimation error $e_t$.

3 Observability and Sensitivity Properties

To start the discussion, we use the following assumptions and definitions.

**Assumption 1 (System Properties)**
- The sets $\Xi$, $\mathcal{H}$ and $U$ are compact.
- Any initial condition $x_0$ and control sequence $u_t$, $t \geq 0$ are such that, for any possible disturbance sequences $\xi_t$, $t \geq 0$, and $\eta_t$, $t \geq 0$, the system trajectory $x_t$, $t \geq 0$, lies in a closed and compact set $\mathcal{X}$.
- The functions $f$ and $h$ are $C^2$ functions with respect to both arguments $x \in \mathcal{X}$ and $u \in \mathcal{U}$. The associated Lipschitz constants are $k_f$ and $k_h$, respectively.

**Definition 1** A continuous function $\varphi : \mathbb{R} \to \mathbb{R}$ is a $K$ function if $\varphi(0) = 0$, $\varphi(s) > 0$, $\forall s > 0$ and it is strictly increasing.

For the sake of simplicity, we will consider a representation of the MHE problem (4) of the form

$$\min_{z_0} J(z_0, \bar{x}_{t-N}, I_t) := \mu \|z_0 - \bar{x}_{t-N}\|^2 + \|y_t - F(z_0, I_t^u)\|^2. \tag{7}$$

The nonlinear mapping $F : \mathbb{R}^{nx} \times \mathbb{R}^{(N-1)nu} \to \mathbb{R}^{ny}$ has the structure

$$F(z_0, I_t^u) := \begin{bmatrix} h(z_0) \\ h \circ f^{u_{t-N}}(z_0) \\ \vdots \\ h \circ f^{u_{t-1}} \circ \ldots \circ f^{u_t-N}(z_0) \end{bmatrix}. \tag{8}$$

To simplify the analysis, we will also make the following assumption:

**Assumption 2 (Constraints)** The constraints $z_k \in \mathcal{X}$, $k = 0, \ldots, N$ in (4) can be satisfied implicitly, and the optimal estimates never lie at the boundary of the set $\mathcal{X}$.

Later we will discuss extensions needed in order to relax this assumption. We emphasize that formulation (7) is only conceptual. Because of computational efficiency reasons, problem (4) should be solved in practice. We now impose requirements on the observability properties of the nonlinear discrete-time system (1) and relate them to the properties of (7).
Definition 2 (Observability Definition) [8, 3, 4] The system \((1)\) is said to be observable in \(N + 1\) steps if there exists a \(K\)-function \(\varphi(\cdot)\) such that

\[
\|F(z_0, I^u) - F(z'_0, I^u)\|_2 \geq \varphi(\|z_0 - z'_0\|_2^2), \quad \forall z_0, z'_0 \in X, \forall u \in U. \tag{9}
\]

Assumption 3 (Observability Assumption)

System \((1)\) is observable in \(N + 1\) steps \(\forall z_0 \in X\) and \(\forall u \in U\).

This assumption implies that \(\forall z_0, z'_0 \in X\) and \(\forall u \in U\), \(\exists \delta > 0\) such that

\[
\|F(z'_0, I^u) - F(z_0, I^u)\|_2 \geq \delta \|z'_0 - z_0\|_2. \tag{10}
\]

In other words, Assumption 3 guarantees that different initial states give rise to distinguishable output trajectories. This also implies that the system

\[
I^u = F(z_0, I^u), \quad \forall z_0 \in X, \forall u \in U \tag{11}
\]

always has a unique solution. An issue related to Definition 2 is that it can be difficult to verify and quantify in practice (e.g., for large-scale nonlinear systems and in the presence of constraints). Motivated by this, we seek to relate the observability properties of the system to the numerical properties of the NLP problem because this can be verified more easily in practice. Note that uniqueness of (11) is equivalent to guaranteeing that the unregularized \((\mu = 0)\) MHE problem (7) has a unique solution. In optimization literature it is said that the NLP has a strict isolated minimizer. A strict isolated minimizer satisfies the so-called strong second-order sufficient conditions (SSOC), which we present here in the context of problem (7).

Lemma 1 (SSOC Conditions) [9] Let \(J(z_0, \bar{x}, I)\) be a \(C^2\) function w.r.t. \(z_0\) in a neighborhood of \(z_0^o\). Under Assumption 2, if \(\varphi^o := \nabla z J(z_0^o, \bar{x}, I) = 0\) and \(w^T H^o w > 0\) with \(H^o := \nabla_{z, z} J(z_0^o, \bar{x}, I)\) hold \(\forall w\), then \(z_0^o\) is a strict isolated minimizer.

The requirement of \(J(z_0, \bar{x}, I)\) being a \(C^2\) function follows from Assumption 1. The above lemma can be modified to account explicitly for active constraints at the solution. In such a case, the vector \(w\) needs to be restricted to the subspace of the variables at the boundary of \(X\). The analysis of this case would require a detailed structural analysis of the mapping \(F(\cdot, \cdot)\) and of the set \(X\). Therefore, this analysis is omitted here. A detailed SSOC analysis in the context of MHE can be found in Chapters 3 and 6 in [10].

The gradient and the Hessian matrix evaluated at the solution \(z_0^o\) are given by

\[
\nabla_z J(z_0^o, \bar{x}, I) = 2\mu(z_0^o - \bar{x}) - 2 \frac{\partial F^T}{\partial z_0} (I^u - F(z_0^o, I^u)), \tag{12a}
\]

\[
\nabla_{z, z} J(z_0^o, \bar{x}, I) = 2\mu_n + 2 \frac{\partial F^T}{\partial z_0} \frac{\partial F}{\partial z_0} - 2 \frac{\partial^2 F}{\partial z_0^2} (I^u - F(z_0^o, I^u)), \tag{12b}
\]

where \(\frac{\partial F}{\partial z_0}\) and \(\frac{\partial F^T}{\partial z_0} \frac{\partial F}{\partial z_0}\) are the so-called observability and Grammian matrices, respectively. If we apply a second-order Taylor series expansion of the objective function around \(z_0^o\)
Figure 1: Sketch of curvature of cost function for observable ($\lambda_{\text{min}} > 0$) and unobservable system ($\lambda_{\text{min}} = 0$).

satisfying SSOC, we have

\[
J(z_0', \bar{x}, I) - J(z_0^o', \bar{x}, I) = \frac{1}{2} (z_0' - z_0^o)^T H^o (z_0' - z_0^o) \\
\geq \frac{1}{2} \lambda_{\text{min}}(H^o) \| z_0' - z_0^o \|^2,
\]

where $\lambda_{\text{min}}(H^o) > 0$ if SSOC holds (see Figure 1). From (12a) it is not difficult to see that, for the special case in which $\theta = 0$ and the residuals $I^y - F(z_0^o, I^u)$ vanish at the solution, solving problem (7) is equivalent to solving (11). The estimation strategy presented in [1] is based on the solution of this algebraic system. Note also that, in this special case, expression (13) reduces to (10) with $\delta = \frac{1}{2} \lambda_{\text{min}}(H^o)$. Moreover, the Hessian reduces to $H^o = 2 \frac{\partial F}{\partial z_0}^T \frac{\partial F}{\partial z_0}$. Therefore, SSOC implies that the observability matrix is full rank and that the Grammian is positive definite. This was also noticed in [2] in the context of linear systems. From this sequence of implications it is clear that the satisfaction of SSOC is a valid and general observability qualification. Observability properties have been traditionally analyzed a priori by using, for instance, a singular-value-decomposition (SVD) of the Grammian matrix at nominal state and control values. In nonlinear systems, however, it is well known that the system properties can change drastically with the nominal values. In addition, the numerical properties of the Grammian matrix can be related to Definition 2 only if the system model and output mappings are linear. Finally, computing the derivatives of the mapping $F(\cdot, \cdot)$ and performing the SVD decomposition can become expensive or cumbersome in large systems. The SSOC property, on the other hand, can be checked for complex MHE problems through modern NLP solvers and modeling capabilities [10]. This check can be performed a posteriori by solving the estimation problem. This can be useful, for instance, if the available measurements are noisy or if constraints are present.

Remark: To check for the observability qualification through SSOC we require the regularization term to be zero ($\mu = 0$). If the system is already observable, in the sense of Definition 2, setting $\mu > 0$ will introduce a bias in the solution (i.e., this acts as a Tikhonov regularization) [11]. If the system is not observable, setting $\mu$ to a sufficient large value adds artificial curvature to the cost function, inducing a unique (but biased) solution. This regularization term can also be added internally by some NLP algorithms (e.g., a la
Figure 2: Sketch of path of minimizers $z^0(I_t)$ and presence of singular point (loss of observability).

Levenberg-Marquardt) [9] as the search proceeds.

The satisfaction of SSOC also has implications on the sensitivity of the solution to perturbations on the problem data $I$ around a reference solution $z^0(I)$ [12]. To explore this, we use the following well-known result, adapted to the context of problem (7).

**Theorem 2 (NLP Sensitivity) [13, 14].** If a nominal solution $z^0(I)$ satisfies SSOC, then the following hold:

- For $I$ in a neighborhood of $\bar{I}$ there exists a unique, continuous and differentiable vector function $z^0_I(I)$ that is a strict isolated minimizer satisfying SSOC.
- The optimal cost is locally Lipschitz in a neighborhood of $\bar{I}$.

From these results, we can apply the implicit function theorem to (12a) at $z^0(\bar{I})$ to obtain a correction formula (5) with

$$K^o_I = \left. \frac{\partial z^0}{\partial I} \right|_{z^0(I), \bar{x}, \bar{I}} = \mathcal{H}^{-1} \varphi^o_I$$

(14)

and $\varphi^o_I := -\nabla_{z,I} J(z^0(\bar{I}), \bar{x}, \bar{I})$. The sensitivity matrix can be bounded as

$$\left\| \left. \frac{\partial z^0}{\partial I} \right|_{z^0(I), \bar{x}, \bar{I}} \right\| \leq \frac{1}{\lambda_{\text{min}}(\mathcal{H}^o)} \| \varphi^o_I \|.$$  (15)

If the solution satisfies SSOC (system is observable), the solution is *numerically stable* to perturbations on $I$. This is reflected by a small sensitivity matrix. If, on the other hand, the Hessian becomes singular (system becomes unobservable), the sensitivity matrix grows unboundedly. This singularity represents a bifurcation point in the $z^0(I) - I$ space at which solutions of the MHE problem move from a set of minimizers to a set of saddle points or maximizers [15]. This is sketched in Figure 2.

Using the sensitivity results, we can now establish a rigorous bound on the error generated by the correction step of the approximate MHE algorithm.
Lemma 3 (Numerical Error Bound) Assume $z^o_i(I_t)$ is a solution of (7) satisfying SSOC. Then, for $I_t$ in the neighborhood of $I_0$, there exist $k_x, k_J, \epsilon > 0$, such that

\[
\|\hat{x}^o_{t-N}(I_t) - \tilde{x}^o_{t-N}(I_t)\| \leq k_x \|I_t - I_0\|^2 + k_J \|I_t - I_0\|^2. \tag{16a}
\]

\[
\epsilon_t = J(\hat{x}^o_{t-N}(I_t), \tilde{x}^o_{t-N}, I_t) - J(\tilde{x}^o_{t-N}(I_t), \bar{x}^o_{t-N}, I_t) \leq k_J \|I_t - I_0\|^2. \tag{16b}
\]

**Proof:** We note that $\hat{x}^o_{t-N}(I_t) = z^o_i(I_t)$. Bound (16a) follows from Taylor’s theorem [16, 17], while (16b) follows from (16a) and the Lipschitz continuity of the cost, as stated in Theorem 2. The error $\epsilon_t$ is always nonnegative because, if $\hat{x}^o_{t-N}(I_t)$ satisfies SSOC, then $J(\hat{x}^o_{t-N}(I_t), \bar{x}^o_{t-N}, I_t) \leq J(\tilde{x}^o_{t-N}(I_t), \bar{x}^o_{t-N}, I_t)$. $\square$

4 Stability Properties

We now establish stability conditions for the estimation error of the approximate MHE algorithm. We define uniform bounds for the disturbances, the initial estimation error $e^o_0 := \hat{x}^o_0 - x_0$ at $t = 0$, and for the constant $\delta$ in the observability condition (10):

\[
r_\xi := \max_{\xi \in \Xi} \|\xi_t\|, \quad r_\eta := \max_{\eta \in \mathcal{H}} \|\eta_t\|, \quad d_x := \max_{x_0, \bar{x}_0} \|\bar{x}^o_0 - x_0\|, \quad \delta_{\min} := \min_{\delta > 0} \|\delta_t\|. \tag{17}
\]

To establish a reference for the stability conditions of the approximate algorithm, we revisit the stability results of [4] for the optimal MHE algorithm.

**Theorem 4 (Stability of Optimal MHE Algorithm)** If Assumptions 1 and 3 hold, then the optimal cost $J(\hat{x}^o_{t-N}, \bar{x}^o_{t-N}, I_t)$ obtained from the solution of (3) can be bounded as

\[
J(\hat{x}^o_{t-N}, \bar{x}^o_{t-N}, I_t) \leq \mu \|x_{t-N} - \bar{x}^o_{t-N}\|^2 + c^2, \quad I_t \geq 0,
\]

\[
J(\hat{x}^o_{t-N}, \bar{x}^o_{t-N}, I_t) \geq \frac{1}{2} \mu \|e^o_{t-N}\|^2 + \frac{1}{2} \varphi(\|e^o_{t-N}\|^2) - \mu \|x_{t-N} - \bar{x}^o_{t-N}\|^2 - c^2.
\]

Furthermore, the estimator error $e^o_{t-N}$ can be bounded as

\[
\|e^o_{t-N}\|^2 \leq \zeta_{t-N},
\]

where $\zeta_{t-N}$ is generated by the sequence

\[
\zeta_0 = \beta_0 \tag{19a}
\]

\[
\zeta_t = \alpha \zeta_{t-1} + \beta \tag{19b}
\]

\[
\alpha = \frac{4}{\mu + \delta_{\min}} \left(2\mu k_\xi^2\right) \tag{19c}
\]

\[
\beta_0 = \frac{4}{\mu + \delta_{\min}} \left(2\mu d_x^2 + c^2\right) \tag{19d}
\]

\[
\beta = \frac{4}{\mu + \delta_{\min}} \left(2\mu r_\xi^2 + c^2\right). \tag{19e}
\]

If $\mu$ is selected such that $\alpha < 1$, then as $t \to \infty$, we have $\|e^o_\infty\|^2 \to \frac{\beta}{1-\alpha}$.

**Proof:** The complete proof of this theorem has been presented in [4]. A summary is given in Appendix A. $\square$
Note that the above theorem does not make use of Assumption 2. The theorem states that, for a suitable choice of $\theta$, the estimation error sequence is convergent. Condition $\alpha < 1$ becomes easier to satisfy as $\delta_{\text{min}}$ increases (better observability). For $\delta_{\text{min}} = 0$ this condition can be satisfied only if $8k_2^2 < 1$ ($\mu$ cannot be used to control the error). If $\delta_{\text{min}} > -\mu$, the estimator error can still be forced to converge (under very restrictive conditions). The error diverges for $\delta_{\text{min}} \leq -\mu$. This clearly illustrates the role of the regularization or arrival cost term in the cost function. The previous stability result requires the MHE problem to be solved on-line to optimality. We now establish stability conditions for the approximate MHE algorithm. In particular, we analyze the propagation of $\epsilon_t$ through the estimator error sequence.

**Theorem 5** (Stability of Approximate MHE Algorithm) If Assumptions 1 and 3, and the bounds of Lemma 3 hold, then the approximate cost $J(\hat{x}_{t-N}^*, \bar{x}_{t-N}^*, I_t)$ can be bounded as

$$
J(\hat{x}_{t-N}^*, \bar{x}_{t-N}^*, I_t) \leq \mu \|x_{t-N} - \bar{x}_{t-N}^*\|^2 + c^2 + \epsilon_t
$$

$$
J(\hat{x}_{t-N}^*, \bar{x}_{t-N}^*, I_t) \geq \frac{1}{2} \mu \|\epsilon_{t-N}^*\|^2 + \frac{1}{2} \varphi(\|\epsilon_{t-N}^*\|^2) - \mu \|x_{t-N} - \bar{x}_{t-N}^*\|^2 - c^2.
$$

Furthermore, the estimator error $\epsilon_{t-N}^*$ can be bounded as

$$
\|\epsilon_{t-N}^*\|^2 \leq \bar{\zeta}_{t-N},
$$

where $\bar{\zeta}_{t-N}$ is generated by the sequence

$$
\bar{\zeta}_0 = \bar{\beta}_0
$$

$$
\bar{\zeta}_t = \bar{\alpha}\bar{\zeta}_{t-1} + \bar{\beta}
$$

$$
\bar{\beta}_0 = \beta_0 + \frac{4}{\mu + \delta_{\text{min}}} (\kappa_2 r_{\xi}^2 + \kappa_3 r_{\eta}^2)
$$

$$
\bar{\beta} = \beta + \frac{4}{\mu + \delta_{\text{min}}} (\kappa_2 r_{\xi}^2 + \kappa_3 r_{\eta}^2)
$$

$$
\bar{\alpha} = \alpha + \frac{4\kappa_1}{\mu + \delta_{\text{min}}}
$$

with $\kappa_1, \kappa_2$ and $\kappa_3$ defined in Appendix C. If $\mu$ is selected such that $\bar{\alpha} < 1$, then as $t \to \infty$, we have $\|\epsilon_{t-N}^*\|^2 \to \frac{\bar{\beta}}{1 - \bar{\alpha}}$.

**Proof:** See Appendix B. □

**Corollary 6** (Asymptotic Behavior in Absence of Disturbances) If Assumptions 1 and 3, the bounds of Lemma 3, and $r_{\xi} = r_{\eta} = 0$ hold, then $\|\epsilon_{t-N}^o\|^2$ and $\|\epsilon_{t-N}^l\|^2$ converge exponentially to zero as

$$
\|\epsilon_{t-N}^o\|^2 \leq \alpha^{t-N} \beta_0
$$

$$
\|\epsilon_{t-N}^l\|^2 \leq \left(\alpha + \frac{4\kappa_1}{\mu + \delta_{\text{min}}}\right)^{t-N} \beta_0.
$$
**Proof:** In the absence of noise disturbances, we have that $\bar{\beta} = \beta = 0$ and $\bar{\beta}_0 = \beta_0$. The result follows. □

From Corollary 6 we see that the rate of convergence of the approximate estimator is $4\kappa_1/(\mu + \delta_{min})$ slower than that of the optimal counterpart. An unexpected result from this analysis is the fact that, even in the absence of noise disturbances, the rate of convergence of the approximate MHE algorithm is not the same as that of the optimal counterpart. The reason is that the estimation error $||e'_{t-N}||^2$ is always propagated to the predicted output $\bar{y}_{t+1}$ generating an error $\epsilon_{t+1}$ at the next step. For instance, if we have a large initial estimation error (bad initial reference state $\bar{x}_0$), then $||e'_0||^2$ will be large and will tend to give large approximation errors during the first time steps. On the other hand, this also implies that, as soon as $||e'_{t-N}||^2 = 0$, the predicted and true output measurements coincide and $\epsilon_{t+1} = 0$ for all subsequent $t$.

In the presence of noise disturbances, from (19) and (21) it is clear that additional errors are introduced by the correction step. From Appendix C we see that the additional errors are always multiplied by $k_J$. That is, as expected, the stability properties of the estimators coincide if $\epsilon_t = 0$. This happens, for instance, if the model and output mappings are linear, since the MHE problem reduces to a quadratic programming problem and the correction step is exact.

The bounds of Lemma 3 are related to the observability properties of the system and on the numerical stability properties of the MHE problem. Therefore, these bounds are problem dependent. However, from (15) and (5) it is clear that $\epsilon_t$ tends to zero as $\lambda_{min}(H^o)$ shifts away from zero. This means that, as the numerical stability properties of the problem improve, the correction step (5) will not generate appreciable changes in the state estimate. This desired effect can be influenced by increasing the horizon length or by increasing the regularization term $\mu$, since this tends to increase the curvature of the solution, which is reflected in $\lambda_{min}(H^o)$. This behavior can also be appreciated from term $4\kappa_1/(\mu + \delta_{min})$, which tends to decrease as $\delta_{min}$ and $\mu$ increase.

### 5 Numerical Case Study

In this section, we illustrate the effect of numerical errors on the performance of the approximate MHE estimator and discuss some of the the stability properties developed in the previous sections. We consider a simulated MHE scenario on the nonlinear continuous stirred tank reactor [18]:

\[
\begin{align*}
\frac{dx^1}{d\tau} &= \frac{x^1(\tau) - 1}{\theta} + k_0 \cdot x^1(\tau) \cdot \exp \left[ -\frac{E_a}{x^2(\tau)} \right] \\
\frac{dx^2}{d\tau} &= \frac{x^2(\tau) - x_f^2}{\theta} - k_0 \cdot x^1(\tau) \cdot \exp \left[ -\frac{E_a}{x^2(\tau)} \right] + \alpha \cdot u(\tau) \cdot (x^2(\tau) - x_{cw}^2).
\end{align*}
\]

(22a)

(22b)

The system involves two states $x = [x^1, x^2]$ corresponding to the concentration and temperature, respectively, and one control $u$ corresponding to the cooling water flowrate. The continuous-time model is transformed into a discrete-time form through an implicit Euler discretization scheme. The temperature is used as the measured output ($y_t = x_f^2$) to infer the concentration. The model parameters are $x_{cw}^2 = 0.38$, $x_f^2 = 0.395$, $E_a = 5$, $\alpha = 0.38$, $x^1(0) = 0.395$, $x^2(0) = 0.395$. The initial state is $x(0) = [0.395, 0.395]$. The control is applied at $u(0) = 0.38$. The regularization term is $\mu = 0.38$. The horizon length is $H = 5$. The model and output mappings are linear.
\(\alpha = 1.95 \times 10^4\), and \(k_0 = 300\). We use batch data generated from a simulated closed-loop feedback control scenario. The simulated states are corrupted with different levels of Gaussian noise with variance \(\sigma^2\) measured as a percentage relative to the nominal temperature value. The corrupted temperature values are used to study the effect of noise disturbances \(\eta_t\). We use \(\bar{x}_0 = [0.15 \ 0.15]\) as the initial reference state, a regularization penalty \(\theta = 30\), and an estimation horizon \(N = 5\).

In Figure 3 we compare the performance of both the optimal and approximate MHE algorithms in the absence of disturbances (\(\sigma^2 = 0\%\)). In the top graph, we present the approximate cost \(J^\epsilon_t := J(\hat{x}_t|\bar{x}_{t-N}, \bar{x}_{t-N}, I_t)\) and its corresponding upper and lower bounds. These bounds correspond to the right-hand sides of equations (32) and (33), respectively. The estimator recovers from the bad initial reference (bound \(d_x\) in Theorem 5), and the estimator error converges to the origin in about 30 time steps (reflected as a zero cost). In the middle graph, we contrast the trajectories of the inferred state for the optimal and approximate estimators, while in the bottom graph we contrast the predicted \(\tilde{y}_t\) and true measurements \(y_t\). These generate the perturbation \(||y_t - \tilde{y}_t||^2\) in (16) for the approximate estimator. As can be seen, even if the initial prior is far away from the true state, both estimators exhibit the same performance. This implies that the errors \(\epsilon_t\) are negligible.

In Figure 4 we compare the performance of the estimators in the presence of noise disturbances with \(\sigma = 2.5\%\). In the top graph, we present the approximate cost and cor-
responding upper and lower bounds in which we can see that the estimator converges to a neighborhood of the origin. In the middle graph, we see that the trajectories of the inferred state for both estimators are still very close to each other. In the bottom graph, we present the relatively large perturbations $\|y_t - \bar{y}_t\|^2$ reflected by larger deviations between the predicted and true temperatures compared to those observed in the noise-free scenario.

In the top graph of Figure 5 we present the total sum of the approximation errors $\epsilon_{\text{sum}} = \sum_t \epsilon_t$ over the whole horizon for scenarios with increasing levels of noise $\sigma^2 = [0\% , 2.5\% , 5\% , 7.5\% , 10\% ]$. As expected, the approximation errors tend to increase with the noise level. Nevertheless, their overall magnitude remains small $O(10^{-5})$. This is mainly due to the good observability properties of the system. To illustrate this, in the bottom graph we present trends of $\lambda_{\text{min}}(\mathcal{H}_\theta)$ for MHE problems with different horizons and two different regularization terms. As can be seen, for the $\mu = 0$ case, the system is observable even for very short horizons ($\lambda_{\text{min}}(\mathcal{H}_\theta) > 0$). This value also increases with the horizon length, as expected. Note also that, by setting $\mu = 1$, the eigenvalues are shifted away from zero. However, the relationship is not one-to-one because of the nonlinearity of the system. From bound (15), it can be seen that this tends to decrease the sensitivity of the state estimates and thus reduce the approximation errors.
6 Conclusions and Future Work

In this work, we have studied the stability properties of an approximate algorithm for moving horizon estimation (MHE). The algorithm is particularly suitable for large-scale systems because it can significantly reduce the on-line solution time by constructing fast approximations using reference solutions computed in between sampling times. The stability analysis reveals that the estimation error converges at a similar rate compared to that of an optimal MHE counterpart. In addition, the observability properties of the nonlinear system have a strong impact on the convergence of the estimator error. This insight has been used to derive guidelines able to reduce the impact of numerical errors.

As part of future work, we are interested in considering the more general MHE formulation presented in [3]. We recognize that, for strong disturbances or ill-conditioned problems, the corrected state $\hat{x}(I_t)$ in (5) can become a worse approximation than the uncorrected state $x(I_t)$ if error bounds of Lemma 3 do not hold. We are thus interested in developing strategies able to preserve stability.

A Proof of Theorem 4

To construct the estimator error sequence $e_{t-N}^o$, we obtain lower and upper bounds for the cost function $J(\hat{x}_{t-N}^o, \bar{x}_{t-N}^o, I_t)$. An upper bound can be obtained by noticing that, since $\hat{x}_{t-N}^o$ is optimal, it gives a smaller cost than the true state $x_{t-N}$ (because of the regularization term). With this,

$$J(\hat{x}_{t-N}^o, \bar{x}_{t-N}^o, I_t) \leq J(x_{t-N}, \bar{x}_{t-N}^o, I_t) = \mu\|x_{t-N} - \bar{x}_{t-N}^o\| + ||I_t^o - F(x_{t-N}, I_t^o)\|^2.$$  (23)

As shown in equation (32) in [4], the second term on the right-hand side can be bounded by using the disturbance bounds $r_\xi$ and $r_\eta$. These terms can be lumped into a constant $c^2$ to give

$$J(\hat{x}_{t-N}^o, \bar{x}_{t-N}^o, I_t) \leq \mu\|x_{t-N} - \bar{x}_{t-N}^o\| + c^2.$$  (24)

To construct a lower bound, we start from the optimal cost,

$$J(\hat{x}_{t-N}^o, \bar{x}_{t-N}^o, I_t) = \mu\|\hat{x}_{t-N}^o - \bar{x}_{t-N}^o\| + ||I_t^o - F(\hat{x}_{t-N}^o, I_t^o)\|^2.$$  (25)

The second term can be bounded from

$$\|F(x_{t-N}, I_t^o) - F(\hat{x}_{t-N}^o, I_t^o)\|^2 = \|\left(I_t^o - F(\hat{x}_{t-N}^o, I_t^o)\right) + \left(F(x_{t-N}, I_t^o) - I_t^o\right)\|^2 \leq 2\|I_t^o - F(\hat{x}_{t-N}^o, I_t^o)\|^2 + 2c^2$$  (26)

so that

$$\|I_t^o - F(\hat{x}_{t-N}^o, I_t^o)\|^2 \geq \frac{1}{2}\|F(x_{t-N}, I_t^o) - F(\hat{x}_{t-N}^o, I_t^o)\|^2 - c^2 \geq \frac{1}{2}\phi(\|x_{t-N} - \hat{x}_{t-N}^o\|^2) - c^2.$$  (27)

The last inequality arises from the Observability Assumption 3. We now bound the first term in (25) from

$$\mu\|\hat{x}_{t-N}^o - \hat{x}_{t-N}^o\| \leq 2\mu\|x_{t-N} - \hat{x}_{t-N}^o\| + 2\mu\|\hat{x}_{t-N}^o - \bar{x}_{t-N}^o\|$$

$$\mu\|\hat{x}_{t-N}^o - \bar{x}_{t-N}^o\| \geq \frac{1}{2}\mu\|x_{t-N} - \hat{x}_{t-N}^o\| - \mu\|x_{t-N} - \bar{x}_{t-N}^o\|.$$  (28)

Merging terms and using (10) with $\delta_{min}$, we obtain

$$J(\hat{x}_{t-N}^o, \bar{x}_{t-N}^o, I_t) \geq \frac{1}{2}\mu||e_{t-N}^o|| + \frac{1}{2}\delta_{min}\|e_{t-N}^o\|^2 - \mu\|x_{t-N} - \bar{x}_{t-N}^o\| - c^2.$$  (29)

Combining bounds (25) and (29) yields

$$\frac{1}{2}\mu||e_{t-N}^o|| + \frac{1}{2}\delta_{min}\|e_{t-N}^o\|^2 \leq 2\mu\|x_{t-N} - \hat{x}_{t-N}^o\| + 2c^2 \leq \frac{4\mu}{\mu + \delta_{min}}\|x_{t-N} - \tilde{x}_{t-N}^o\|^2 + \frac{4}{\mu + \delta_{min}}c^2.$$  (30)
The proof is completed by relating the current estimation error to the previous estimation error as

\[
\|x_{t-N} - \tilde{x}_{t-N}\|^2 = \|f(x_{t-N-1}, u_{t-N-1}) + \xi_{t-N} - f(\tilde{x}_{t-N-1}, u_{t-N-1})\|^2 \\
\quad \leq 2k_f^2 \|x_{t-N-1} - \tilde{x}_{t-N-1}\|^2 + 2\|\xi_{t-N-1}\|^2 \\
\quad = 2k_f^2 \|e_{t-N-1}\|^2 + 2\|\xi_{t-N-1}\|^2. \tag{31}
\]

The convergent sequence follows from (30) and (31). The proof is complete. □

**B Appendix - Proof of Theorem 5**

A lower bound for the approximate cost \(J(\hat{x}_{t-N}^e, \bar{x}_{t-N}^e, I_t)\) can be obtained as in Appendix A to give

\[
J(\hat{x}_{t-N}^e, \bar{x}_{t-N}^e, I_t) \geq \frac{1}{2} \mu \|e_{t-N}^e\|^2 + \frac{1}{2} \delta_{\min}(\|e_{t-N}^e\|^2) - \mu \|x_{t-N} - \bar{x}_{t-N}^e\|^2 - c^2. \tag{32}
\]

As an upper bound we consider

\[
J(\hat{x}_{t-N}^e, \bar{x}_{t-N}^e, I_t) = J(\tilde{x}_{t-N}, \bar{x}_{t-N}, I_t) + \epsilon_t. \tag{33}
\]

With this,

\[
J(\hat{x}_{t-N}^e, \bar{x}_{t-N}^e, I_t) \leq \mu \|x_{t-N} - \bar{x}_{t-N}^e\|^2 + c^2 + \epsilon_t. \tag{34}
\]

Combining the upper and lower bounds, we have

\[
\mu \|x_{t-N} - \bar{x}_{t-N}^e\|^2 + c^2 + \epsilon_t \geq \frac{1}{2} \mu \|e_{t-N}^e\|^2 + \frac{1}{2} \delta_{\min}(\|e_{t-N}^e\|^2) - \mu \|x_{t-N} - \bar{x}_{t-N}^e\|^2 - c^2 \\
\|e_{t-N}^e\|^2 \leq \frac{4\mu}{\mu + \delta_{\min}} \|x_{t-N} - \bar{x}_{t-N}^e\|^2 + \frac{4}{\mu + \delta_{\min}} c^2 + \frac{2}{\mu + \delta_{\min}} \epsilon_t. \tag{35}
\]

The first term on the right-hand side is bounded as

\[
\|x_{t-N} - \bar{x}_{t-N}^e\|^2 \leq 2k_f^2 \|e_{t-N-1}\|^2 + 2r_f^2. \tag{36}
\]

To bound \(\epsilon_t\), we first note that the only element changing from \(I_t\) is the predicted measurement \(\bar{y}_t\) which is computed from extrapolation of the previous state estimate \(\hat{x}_{t-1}^e\). With this, (16) reduces to

\[
\epsilon_t \leq k_f \|\bar{y}_t - y_t\|^2. \tag{37}
\]

The error between measurements is bounded as

\[
\|\bar{y}_t - y_t\|^2 = \|h(f(\hat{x}_{t-1}^e, u_{t-1})) - h(f(x_{t-1}, u_{t-1}) + \xi_{t-1}) + \eta_{t-1}\|^2 \\
\quad \leq 2k^2_h (2k_f^2 \|e_{t-1}^e\|^2 + 2\|\xi_{t-1}\|^2) + 2\|\eta_{t-1}\|^2 \\
\quad \leq 4k^2_h k_f^2 \|e_{t-1}^e\|^2 + 4k^2_h r_f^2 + 2r_{\eta}^2. \tag{38}
\]

15
where $e_{t-1}^\epsilon$ is the estimation error of the state $\hat{x}_{t-1}^\epsilon$ obtained from propagation of the initial state $\hat{x}_{t-N-1}^\epsilon$. As a consequence, this error can be related to the desired estimation error $e_{t-N-1}^\epsilon$ through backpropagation:

$$\|e_{t-1}^\epsilon\| = \|\hat{x}_{t-1}^\epsilon - x_{t-1}\|^2$$

$$= \|f(\hat{x}_{t-2}^\epsilon, u_{t-2}) - f(x_{t-2}, u_{t-2}) - \xi_{t-2}\|^2$$

$$\leq 2k_f^2\|e_{t-2}^\epsilon\|^2 + 2\|\xi_{t-2}\|^2$$

$$\leq 2k_f^2\|f(\hat{x}_{t-3}^\epsilon, u_{t-3}) - f(x_{t-3}, u_{t-3}) + \xi_{t-3}\|^2 + 2\|\xi_{t-2}\|^2$$

$$\vdots$$

$$\leq (2k_f^2)^N\|e_{t-N-1}^\epsilon\|^2 + \sum_{k=0}^{N-1} (2k_f^2)^k r_k^2$$

$$= (2k_f^2)^N\|e_{t-N-1}^\epsilon\|^2 + \frac{(2k_f^2)^N - 1}{2k_f^2 - 1} r_0^2.$$  \hspace{1cm} (39)

With this,

$$\|\hat{y}_t - y_t\|^2 \leq 4k_k^2k_f^2\|e_{t-1}^\epsilon\|^2 + 4k_h^2r_\eta^2 + 2r_\eta^2$$

$$\leq 4k_k^2k_f^2 \left((2k_f^2)^N\|e_{t-N-1}^\epsilon\|^2 + \frac{(2k_f^2)^N - 1}{2k_f^2 - 1} r_0^2\right) + 4k_h^2r_\eta^2 + 2r_\eta^2$$

$$\leq 2k_h^2(2k_f^2)^{N+1}\|e_{t-N-1}^\epsilon\|^2 + 2k_h^2 \left(2 + \frac{(2k_f^2)^N - 1}{2k_f^2 - 1}\right) r_\eta^2 + 2r_\eta^2.$$  \hspace{1cm} (40)

We have thus obtained the required bound for $\epsilon_t$:

$$\epsilon_t \leq 2\kappa_1\|e_{t-N-1}^\epsilon\|^2 + 2\kappa_2r_\xi^2 + 2\kappa_3r_\eta^2.$$  \hspace{1cm} (42)

Substituting (42) and (36) in (35), we have

$$\|e_{t-N}^\epsilon\|^2 \leq \frac{4\mu}{\mu + \delta_{\text{min}}} \left(2k_f^2\|e_{t-N-1}^\epsilon\|^2 + 2r_\xi^2\right) + \frac{4}{\mu + \delta_{\text{min}}} c^2$$

$$+ \frac{2}{\mu + \delta_{\text{min}}} \left(2\kappa_1\|e_{t-N-1}^\epsilon\|^2 + 2\kappa_2r_\xi^2 + 2\kappa_3r_\eta^2\right)$$

$$= \left(\frac{8k_f^2\mu}{\mu + \delta_{\text{min}}} + \frac{4\kappa_1}{\mu + \delta_{\text{min}}}\right)\|e_{t-N-1}^\epsilon\|^2 + \frac{4}{\mu + \delta_{\text{min}}} \left(2\mu r_\xi^2 + c^2\right)$$

$$+ \frac{4}{\mu + \delta_{\text{min}}} (\kappa_2r_\xi^2 + \kappa_3r_\eta^2),$$  \hspace{1cm} (43)
where $\kappa_1$, $\kappa_2$, and $\kappa_3$ are defined in Appendix C. The error sequence follows:

$$
\|e_{t-N}\|^2 \leq \tilde{\zeta}_{t-N}
$$

$$
\tilde{\zeta}_0 = \tilde{\beta}_0
$$

$$
\tilde{\zeta}_t = \ddot{\alpha} \tilde{\zeta}_{t-1} + \ddot{\beta}
$$

$$
\tilde{\beta}_0 = \beta_0 + \frac{4}{\mu + \delta_{\min}} (\kappa_2 r_\xi^2 + \kappa_3 r_\eta^2)
$$

$$
\ddot{\beta} = \beta + \frac{4}{\mu + \delta_{\min}} (\kappa_2 r_\xi^2 + \kappa_3 r_\eta^2)
$$

$$
\ddot{\alpha} = \alpha + \frac{4\kappa_1}{\mu + \delta_{\min}}.
$$

The proof is complete. \qed

C Constants

$$
\kappa_1 = k_J k_h^2 (2k_f)^{N+1}
$$

$$
\kappa_2 = k_J k_h^2 \left( 2 + \frac{(2k_f)^{N+1} - 1}{2k_f^2 - 1} \right)
$$

$$
\kappa_3 = k_J.
$$
